 Re: Santa Ana Sucker (*Catostomus santaanae*) Final Report Report: 2011 - 2012

## Santa Ana Sucker Population Monitoring 2001-2011

2011 is the eleventh year San Marino Environmental Associates (SMEA) has monitored. *Catostomus santaanae* (Santa Ana sucker) populations in the Santa Ana River: Site 1, upstream of Mission Boulevard Bridge; Site 2, just downstream of Highway 60 Bridge; and Site 3, downstream of Riverside Avenue Bridge. A fourth site, MWD crossing, was added to the monitoring protocol in 2010 and it has been surveyed for the last two years. Fish densities within each 100-meter site were determined using maximum likelihood methods based on a multiple-pass depletion methodology. Fish captured per 100m were then converted to an estimate of fish population density per mile

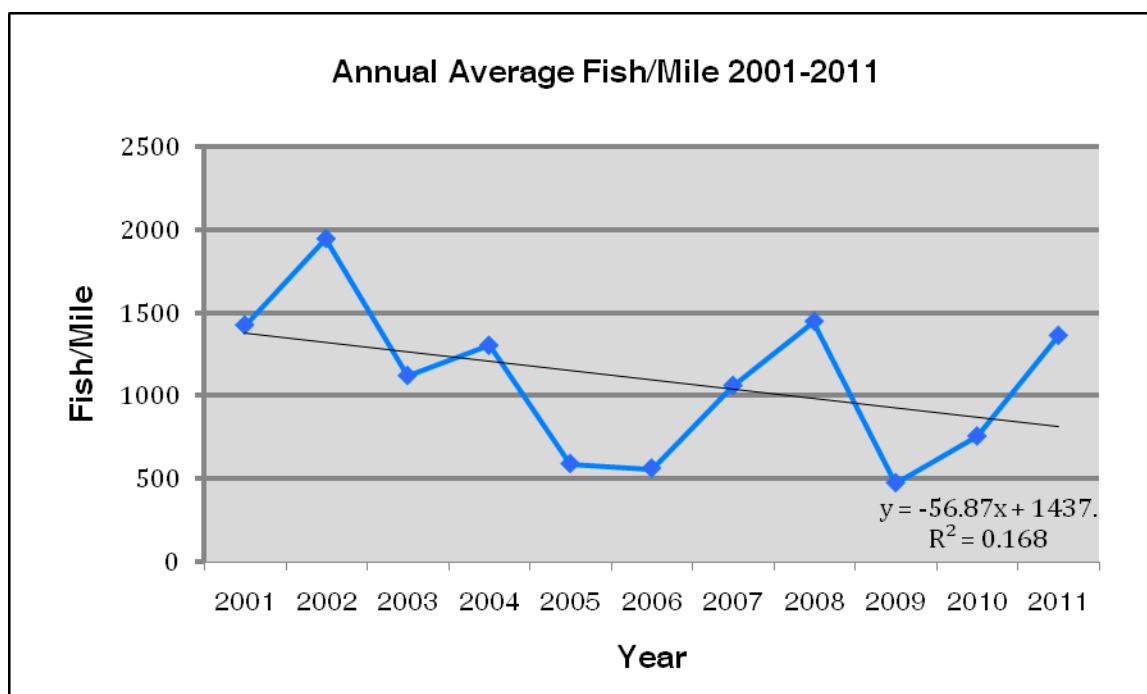

### Sucker Ana Sucker Population Data

**Table 1.** Santa Ana sucker, *Catostomus santaanae*, abundance expressed as fish/mile at the three monitoring sites over the 11-year period, 2001-2011; and 2 years of monitoring at MWD crossing.

	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011
<b>Mission Blvd</b>	1,432	2,350	1,014	32	16	0	0	580	16	64	595
<b>Highway 60</b>	2,639	2,736	1,545	3,235	16	0	1,625	322	528	0	772
<b>Riverside Ave</b>	209	756	805	644	1,579	1,689	1,561	3,445	880	2,108	3,718
<b>MWD Crossing</b>										853	370
<b>Average (w/MWD)</b>	<b>1,427</b>	<b>1,947</b>	<b>1,121</b>	<b>1,304</b>	<b>537</b>	<b>563</b>	<b>1,062</b>	<b>1,449</b>	<b>475</b>	<b>724 (756)</b>	<b>1,695 (1,364)</b>

Over the first five sampling seasons (2001-2005), fish density decreased by a factor of almost 3 and then stabilized (2005-2006). By the next sampling season (2007) and through the 2008, fish density had increased but by 2009 it decreased precipitously to the lowest value recorded (475

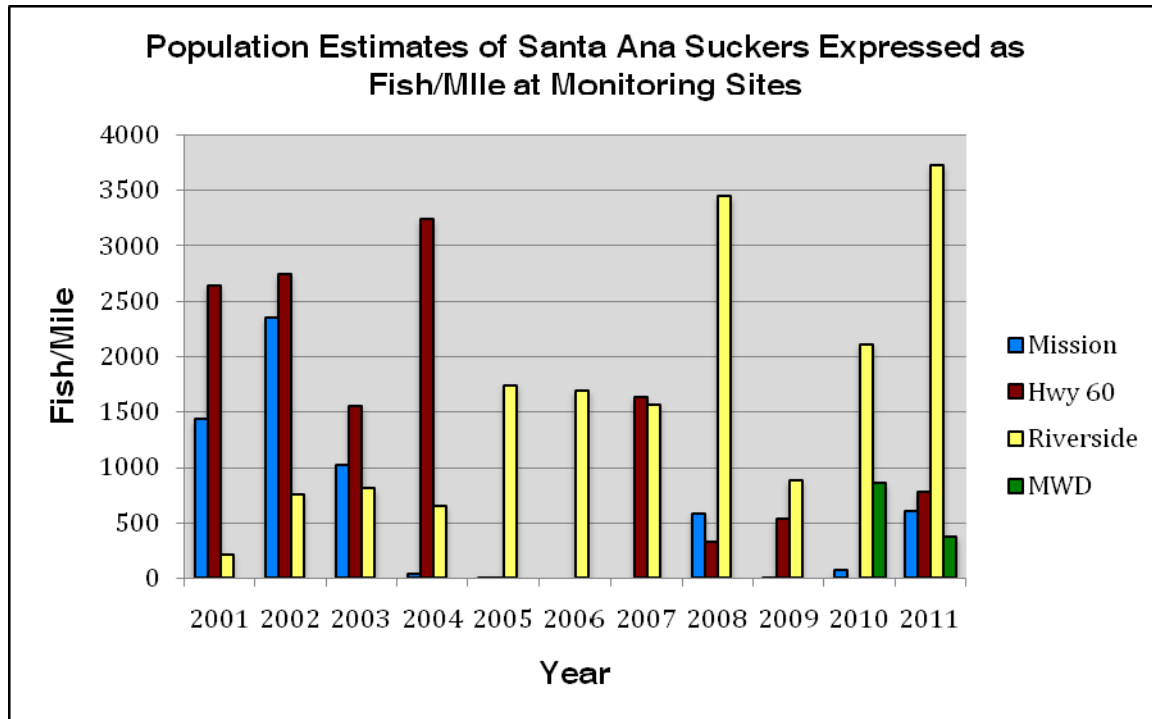

fish/mile) since annual surveys began in 2001. Fish populations have since recovered (2010-2011) to densities similar to when monitoring first began in 2001. Long term monitoring indicates that there is substantial year-to-year variability in fish density within the Santa Ana River. A variety of statistical techniques including an autoregressive integrative moving average, autocorrelation using the Durbin-Watson statistic, spectral analysis and polynomial regression were used to try and detect periodicity or time related trends in average fish density. In no case was a pattern, periodicity, nor any pattern that would be expected if periodicity were present, detected in the data set.

**Figure 1.** Annual average estimate of Santa Ana suckers, *Catostomus santaanae*, per mile of river based on the population estimates at the three long-term monitoring sites over the 11-year period from 2001-2011.

*C. santaanae* densities vary annually at each monitoring site. At the downstream site (Mission Boulevard) densities increased 2001 to 2001 but then declined from 2003-2005 to 16 fish per mile, and were absent between 2006 and 2007. Fish returned to the Mission Boulevard site in 2008, but density has since been low and highly variable (2009-2011). At the midstream site (Highway 60) fish densities have been highly variable year to year. Initial densities at the site from 2001-2001 were high, ranging from 1545 to 3235 fish per mile, dropped precipitously to 16 fish per mile in 2005 and declined to zero by 2006. Fish density recovered to 1625 fish per mile in 2007 but again declined through 2008 and 2009 to 322 and 528 fish per mile, respectively. In 2010 no fish were captured at the site but by 2011 fish densities had recovered to 772 fish per mile. Fish densities generally increased from 2001 to 2005 at the most upstream site (Riverside Drive), remained stable through the next two years 2006-2007 and then increased to 3445 fish per mile by 2008. Density has since fluctuated (2009-2010) but by 2011 had increased to 3718 fish per mile, the highest levels observed at any of the three monitoring sites during the eleven

sampling seasons. In 2010 a fourth site, MWD crossing, was added to the monitoring protocol. Density in 2010 was 853 fish per mile and then dropped to 370 fish per mile by 2011.

**Figure 2.** Population estimate of Santa Ana sucker, *Catostomus santaanae*, expressed as fish/mile at the three long-term monitoring sites over the 11 year period, 2001-2011.

Analysis of Covariance (ANCOVA) was used to examine trends in sucker density at monitoring sites over time. There is a highly significant site by time interaction, which indicates that the density (fish/mile) at a site (Mission, Hwy 60, Riverside and MWD) is dependent on time. The whole model regression plot (Figure 3) shows that site 1 (Mission), site 2 (Highway 60) and site 4 (MWD crossing) have declined in sucker density over time whereas site 3 (Riverside) has increased in density over time.

The Effects Test Table shows the level of confidence that we can assign to density patterns among sites over time. The individual effect of site ( $p=0.02$ ) was significant but not the individual effect of time ( $p=0.60$ ) on the mean density of fish. There was, however, a highly significant interaction between year of sampling and sampling location (Time \* Site,  $p=0.0004$ ), because the density of *C. santaanae* declined at Site 1 (Mission) and Site 2 (Highway 60) over 11 sampling seasons and at MWD crossing from 2010-2011, whereas the abundance of *C. santaanae* has increased at Site 3 (Riverside) over 11 sampling seasons.

**Figure 3.** Analysis of covariance (ANCOVA). Response abundance, whole model regression plot (abundance of *Catostomus santaanae* is the estimate of fish per mile over the sampling years 2001-2011).

**Effect Tests**

Source	Nparm	DF	Sum of Squares	F Ratio	Prob > F
Site	3	3	7076499	3.79	0.02
Time	1	1	183885	0.30	0.60
Site*Time	3	3	16031815	8.59	0.0004

Conclusions are:

1. There is substantial year-to-year variability in the density of *C. santaanae* both among and within monitoring sites in the Santa Ana River.

2. The average annual density of *C. santaanae* measured in 2011 is near the highest levels reported since sampling began in 2001. This result, however, must be examined in the context of increasing and decreasing trends in population size among individual monitoring sites. Only one site (Riverside Ave) has consistently shown an increase in fish density from 2001-2011, whereas the Mission Blvd and Highway 60 sites have shown a long term decrease in fish density over this same time period.
3. A new monitoring site (MWD crossing) was established in 2010 and has been surveyed for the last two years. There has been a 57% decrease in *C. santaanae* density at the site from 2010-2011 but a longer time course is necessary to comment on trends in population size.
4. Absence of *C. santaanae* at a monitoring site in any one sampling year does not appear to signal long-term elimination of the species from that locality and often recovery at depauperate sites is significant in the following year. (see Highway 60, 2006-2007)

Re: Draft Progress Report – Periodicity of Sucker Population Data

---

We asked Dr. David Moriarty, Professor of Biological Sciences at Cal Poly University Pomona and an expert on Biometrics, to examine all 11 years of our population estimation data for an evidence of periodicity. As you may recall this question came up at our last team meeting. Below is his response.

November 18, 2011

Jon,

The “executive summary” for the Average variable in the fish data is that there is no evidence of periodicity or time related trends. I would emphasize that a sample size of  $n=11$  is quite low for detecting periodicity.

Here’s more detail on what I did, and the output below.

Page 1

An attempt to identify relationships using an ARIMA (Autoregressive Integrative Moving Average) modeling approach. If there is a periodic relationship, you should be able to detect autocorrelation in the data, i.e. Average at a given time period should be predicted by previous time periods. However, there is very little autocorrelation in the data. The “white noise” test asks whether there is pattern in the data, or if it represents random fluctuations. There is no pattern detected.

Sample size is an issue here. I had the program do the time period lags up to 6 because that is the minimum to get the whitenoise test. However, as stated on the output, the lags generally should not exceed 25% of the series length, which would be a maximum lag of  $\sim 2$  time periods.

The graphs indicate the autocorrelation is very low, even at  $\text{lag}=1$ , indicating the series is not stationary. This is consistent with the white noise conclusion.

Pages 2-3

Use an autoregression approach to try to detect autocorrelation with the Durbin-Watson statistic. I only went to time lag = 3 here, because you quickly run out of degrees of freedom. None of the time lags show anything even close to autocorrelation.

Pages 4-7

Uses spectral analysis to try to detect periodicity. The series is decomposed into a sum of sine and cosine waves using Fourier transforms. It’s sort of like regressing the series – not onto a straight line function – but rather a function involving the sines and cosines. This is done with very small increments to try to fit the series well. The graphs on page 6 and 7 indicate the lack of periodicity. If periodicity were present, the periodgram and spectral density would peak at the value of the period. The near monotonic increase in both graphs indicates lack of periodicity. The spectral analysis also includes tests for white noise: Fisher’s Kappa, and the Bartlett’s Kolmogorov-Smirnov test. I do not have access to a table of significant values of Fisher’s Kappa, but a value of 1.774936 is quite low. It would have to be much higher (at least around 7) to begin to approach significance. The Bartlett’s Kolmogorov-Smirnov has a p value of 0.5543. This would have to be  $\leq 0.05$  to conclude that periodicity was present. As above, the fluctuations appear to be random.

Pages 8-20

As a last resort, I attempted to fit a polynomial regression to the Average data. Polynomial regression would not establish periodicity, but could detect some nonlinear pattern to the change in Average over the years. I fit the polynomial up to degree 5, which is rather aggressive given the sample size of 11. However, no polynomial of any degree, linear through quintic, produced a significant relationship of any kind.

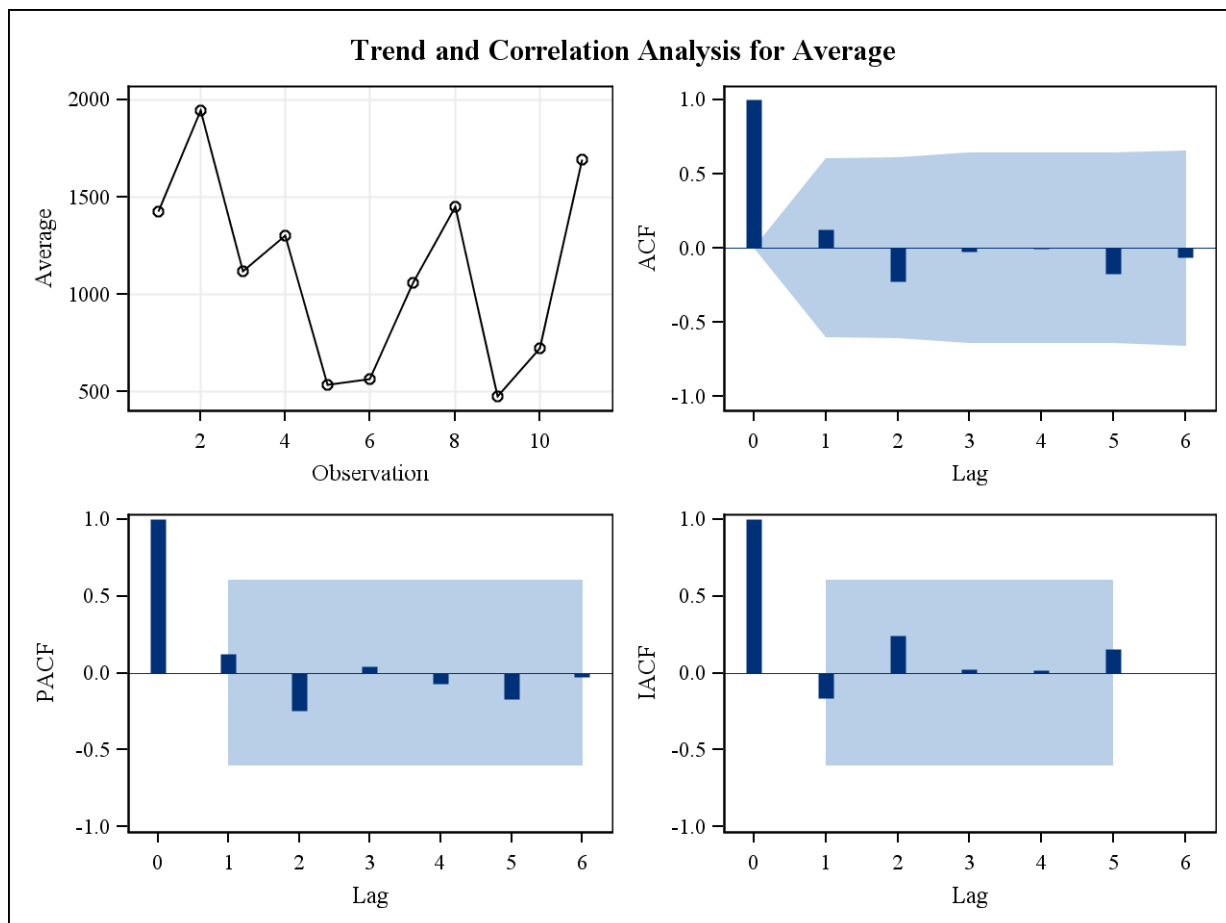

In conclusion, I did not detect any pattern in the data, certainly no periodicity, nor any pattern (e.g. autocorrelation) that would be expected if periodicity were present.

### The ARIMA Procedure

**Warnin** The value of NLAG is larger than 25% of the series length. The asymptotic approximations used for correlation based statistics and confidence intervals may be poor.

From: Dave Moriarty

Re: Santa Ana Sucker data

As a follow-up to discussion and suggestions at the March 15, 2012 meeting of the conservation team, I conducted further analysis on the data. I did not include the MWD site because there are only  $n = 2$  observations from that site.

#### Distribution and Homoscedasticity

In the context of the ANCOVA prepared by Tom Even, the question of data assumptions and transformations was raised. No simple data transformation will normalize the data. However, I used the Box-Cox procedure to identify a transformation ( $\lambda = 0.4099$ ) which was able to normalize the data for all three sites (Shapiro-Wilk Test, all  $P > 0.05$ ). This transformation also produced a normal distribution for eight of the 11 years. The years not normal were 2005, 2006, 2007. I would emphasize that these tests for the years were all based on  $n = 3$ . The transformed data were also homoscedastic for all sites and years (Levene's Test – Brown and Forsythe method,  $P > 0.05$ ).

#### ANCOVA on Transformed Data

I ran the ANCOVA model on the transformed data, with the following results:

Source	DF	Type III SS	Mean Square	F Value	Pr > F
Site	2	3628.770072	1814.385036	6.92	0.0037
Year	1	379.334708	379.334708	1.45	0.2395
Year*Site	2	3636.198663	1818.099332	6.93	0.0037

Notice that the significance of all sources is the same as the ANCOVA provided by Tom that appeared in the original report. That is, there is a significant site and year x site interaction, but

the pooled regression (year) is not significant. The transformed data do not cause any difference in the ANCOVA or in the interpretations provided in the original report.

#### Repeated Measures; Multiple Comparisons

The meeting produced a suggestion that a repeated measures approach be taken with the data. To implement this, I treated both site and year as factors in a two-factor model II ANOVA without replication performed on transformed data. The results were:

Source	DF	Type III SS	Mean Square	F Value	Pr > F
Site	2	2777.406176	1388.703088	3.64	0.0448
Year	10	3466.323902	346.632390	0.91	0.5434

This indicates there is significant variance explained by site, but not by year. Since the notion of multiple comparison tests (specifically LSD and the Tukey HSD) was discussed, I performed those tests as well as nine additional multiple comparison tests. All eleven tests produced the same result, which is that the Riverside and Mission sites were significantly different, with Highway 60 being intermediate and not significantly different from either Riverside or Mission. The site means are provided below for your convenience. I would repeat the point that Tom made in the original report, namely that variation is extremely high. Notice that in the table below, the coefficients of variation are 71.7%, 98.9%, and 138.7%.

Site	N Obs	Mean	Std Dev	Std Error	Coeff of Variation
Riverside	11	1581.3	1134.3	342.0	71.7
Hwy_60	11	1219.8	1206.4	363.7	98.9
Mission	11	554.5	769.1	231.9	138.7

I would be happy to respond to any questions you may have.

Re: Draft Progress Report – Sucker Survey in Sunnyslope Creek

---

On January 18, 2012 four of us, Brett Mills, Cary Galst, Kerwin Russell and Jonathan Baskin, explored the entire length of Sunnyslope Creek, from the confluence with the Santa Ana River main stem to Rubidoux Nature Center, for suckers (*Catostomus santaanae*). We used a common sense seine and a dip net, no electroshocking. Several suckers were found in the lower portion of the creek, within the first 200 meters upstream from the confluence, but no other suckers were seen or captured. The creek in the nature center area was seined especially intensely in several quite good habitat sites. Some particularly good sites there could not be sampled due to

excessively deep water, so we could not rule out the possibility that suckers are present in the creek at the Nature Center.

The suckers captured were juveniles and not tuberculated (see Table 1). One larger sucker was seen but not captured. Suckers were last captured in Sunnyslope Creek at the Nature Center on February 12, 2010 by SMEA by electrofishing. These suckers were tuberculated.

Chubs, *Gila orcutti*, were found throughout the creek.

Table 1. Standard length of the Santa Ana suckers captured and the degree of tuberculation on the anal fin. Data by Brett Mills.

Standard Length (mm)	Tuberculation	Weight (grams)
81	none	6
76	none	7
71	none	7
